Lecture #17: Abstraction Support: Exceptions, Operators, Properties	<pre>Failed preconditions • Part of the contract between the implementor and client is the set of preconditions under which a function, method, etc. is supposed to operate. • Example: class Rational: definit(self, x, y): """The rational number x/y. Assumes that x and y are ints and y != 0.""" • Here, "x and y are ints and y!=0" is a precondition on the client. • So what happens when the precondition is not met?</pre>

 Programmer Errors Python has preconditions of its own. E.g., type rules on operations: 3 + (2, 1) is invalid. What happens when we (programmers) violate these preconditions 	Outside Events • Some operations may entail the possibility of errors caused by the data or the environment in which a program runs. • I/O over a network is a common example: connections go down; data is corrupted. • User input is another major source of error: we may ask to read an integer numeral, and be handed something non-numeric. • Again, what happens when such errors occur?

ing an exception).

• One approach is to take the point of view that when a precondition is violated, all bets are off and the implementor is free to do anything.

Possible Repsonses

- Corresponds to a logical axiom: False \Rightarrow True.
- But not a particularly helpful or safe approach.
- One can adopt a convention in which erroneous operations return special error values.
 - Feasible in Python, but less so in languages that require specific types on return values.
 - Used in the C library, but can't be used for non-integer-returning functions.
 - Error prone (too easy to ignore errors).
 - Cluttered (reader is forced to wade through a lot of error-handling code, a distraction from the main algorithm).
- Numerous programming languages, including Python, support a general notion of *exceptional condition* or *exception* with supporting syntax and semantics that separate error handling from main program logic.

CS61A: Lecture #17 3

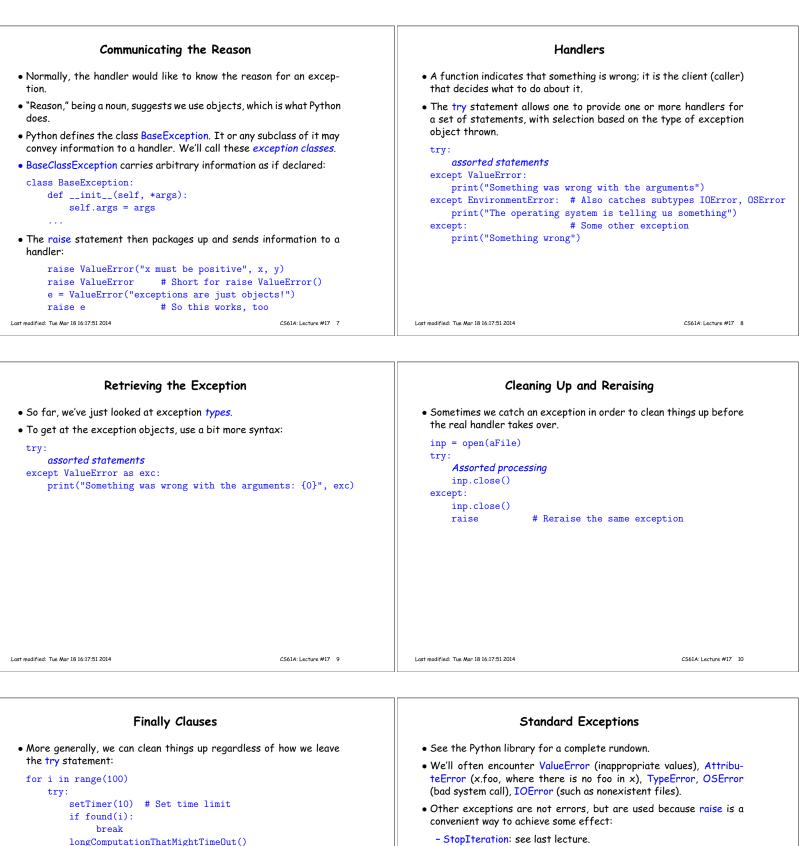

- Resumes execution at some other, previously designated point in the program (called *catching* or *handling* an exception). • In Python, the raise statement throws exceptions, and try statements catch them: def f0(...): try: g0(...) # 1. Call of g... OTHER STUFF # Skipped except: handle oops # 3. Handle problem def g1(...): # Eventually called by g0, possibly many calls down if detectError(): raise Oops # 2. Raise exception MORE # Skipped Last modified: Tue Mar 18 16:17:51 2014 CS61A: Lecture #17 6

Exceptions

- Halts execution at one point in a program (called raising or throw-

• An exception mechanism is a control structure that

Example: Implementing Iterators

- An *iterator* is an abstraction device for hiding the representation of a collection of values.
- The for statement is actually a generic control construct with the following meaning (well, Python adds a few more bells and whistles): tmp_iter = C.__iter__()

except StopIteration:
 pass

CS61A: Lecture #17 13

- The __next__ method can use the raise StopIteration statement to cause the loop to exit.
- Types that implement __iter__ are called *iterable*, and those that implement __next__ are *iterators*.
- The builtin functions iter(x) and next(x) are defined to call x.__iter__() and x.__next__().

for x in C:

S

Problem: Reconstruct the range class
Want Range(1, 10) to give us something that behaves like a Python range, so that this loop prints 1-9:

for x in Range(1, 10):
 print(x)

```
class Range: co
def __init__(self, low, high):
    self._low = low
    self._high = high
def __iter__(self):
    return RangeIter(self)
```

class RangeIter:

def __init__(self, limits):
 self._bound = limits._high
 self._next = limits._low

def __next__(self):
 if self._next >= self._bound:
 raise StopIteration
 else:
 self._next += 1
 return self._next-1

Summary		Back To Rationa	ls
 Exceptions are a way of returning information front of band," and allowing programmers to clearly stabiling from normal cases. In effect, specifying possible exceptions is the interface. Usually, the specification is implicit: one assumes precondition might cause an exception. When a particular exception indicates somethin mally arise (e.g., bad user input), it will often be n in the documentation of a function. Finally, raise and try may be used purely as not tures. By convention, the exceptions used in this "Error." 	eparate error han- refore part of the s that violation of a ng that might nor- nentioned explicitly rmal control struc-	 Before, we implemented rational numbers dard" way is to use a class. Some Basics		Arithmetic	
• We'd like rational numbers, with the usual arithm	• We'd like rational numbers, with the usual arithmetic. • Would be nice to use normal syntax, such as a+b for ratio		as a+b for rationals.

- Furthermore, we'd like to integrate rationals with other numeric types, especially int and float.
- So, let's start with the constructor:

```
class rational:
```

```
def __init__(self, numer=0, denom=1):
```

```
if type(numer) is not int or type(denom) is not int:
    raise TypeError("numerator or denominator not int")
if denom == 0:
    raise ZeroDivisionError("denominator is 0")
```

```
d = gcd(numer,denom)
```

```
self._numer, self._denom = numer // d, denom // d
```

• But we know how to do that from early lectures: def __add__(self, y):

- What do we do if y is an int?
- One solution: *Coercion*:

Coercion	Type Dispatching		
 In programming languages, coercion refers to conversions between types or representations that preserve abstract values. 	 But now what about 3 + rational(1,2)? Ints don't know about ratio- nals. 		
<pre>@staticmethod # Why is this appropriate? def _coerceToRational(y): if type(y) is rational:</pre>	 This is a general problem with object-oriented languages. I call it "worship of the first parameter." It's the type of the first parame- ter (or that left of the dot) that controls what method gets called. 		
return y else: return ?	 Others use the phrase "the expression problem," because it arises in the context of arithmetic-expression-like things. 		
return ?	• There are various ways that languages have dealt with this.		
	 The brute-force solution is to introduce <i>multimethods</i> as a language feature (functions chosen on the basic of all parameters' types.) 		
	 Or one can build something like this explicitly: 		
	<pre>_add_dispatch_table = { (rational, int): _addri,</pre>

A Python Approach	Syntax for Accessors		
• The dispatch-table requires a lot of cooperation among types.	• Our previous implementation of rational numbers had functions for		
 Python uses a different approach that allows extensibility without having to change existing numeric types. 	accessing the numerator and denominator, which now might look like this: def numer(self): """My numerator in lowest terms.""" return selfnumer def denom(self):		
• The expression x+y first tries xadd(y).			
• If that throws the exception NotImplementedError, it next tries yradd_(x).			
 The <u>add</u> functions for standard numeric types observe this, and throw NotImplementedError if they can't handle their right 	"""My denominator in lowest terms.""" return selfdenom		

- It would be more convenient to be able to write simply <u>xnumer</u> and <u>x.denom</u>, but so far, the only way we know to allow this has problems:
 - The attributes are assignable, which we don't want if rationals are to be immutable.
 - We are forced to implement them as instance variables; the implementation has no opportunity to do any calculations to produce the values.
- That is, the syntax exposes too much about the implementation.

Properties	Properties (contd.)	
 To help class implementors control syntax, Python provides an egre- giously general mechanism known as <i>descriptors</i>. 	 The usual shorthand for writing this is to use property as a decora- tor: 	
 An attribute of a class that is set to a descriptor object behaves differently from usual when selected. 	<pre>@property def numer(self): return selfnumer</pre>	
 Descriptors, in their full details, are wonders to behold, so we'll stick with simple uses. 	where the '@' syntax is defined to be equivalent to	
	def numer(self): return selfnumer	
• If we define	<pre>numer = property(numer) # Redefinition.</pre>	
<pre>def numer0(self): return selfnumer numer = property(numer0) # numer is now a descriptor</pre>	 Actually, the builtin property function is even more general. As an example: 	
Then fetching a value x.numer (i.e., without parentheses) is trans- lated to x.numer0().	<pre>class RestrictedInt: """If R is RestrictedInt(L, U), then assign R.x = V first checks that L <= V <= U and then causes R.x to be V."""</pre>	
• Can't assign to it, any more than you can assign to any function call.	<pre>definit(self, low, high): selflow, selfhigh, selfx = low, high, low defgetx(self): return selfx defsetx(self, val): assert selflow <= val <= selfhigh selfx = val x = property(_getx,setx)</pre>
